UNDERBALANCED WELL DRILLING AND PRODUCTIONBackground

This invention relates generally to drilling of wells and production from wells.

Generally, wells are drilled in a slightly over-
5 balanced condition where the weight of the drilling fluid used is only slightly over the pore pressure of the rocks being drilled.

Drilling mud is pumped down the drill string to a drill bit and used to lubricate and cool the drill bit and
10 remove drilled cuttings from the hole while it is being drilled. The viscous drilling mud carries the drilled cuttings upwardly on the outside and around the drill string.

In a balanced situation, the density of the mud going
15 downwardly to the drill bit and the mud passing upwardly from the drill bit is substantially the same. This has the benefit of reducing the likelihood of a so-called kick. In a kick situation, the downward pressure of the drilling mud column is not sufficient to balance the pore pressure in
20 the rocks being drilled, for example of gas or other fluid, which is encountered in a formation. As a result, the well may blowout (if an effective blow out preventer(BOP)is not fitted to the well) which is an extremely dangerous condition.

In underbalanced drilling, the aim is to deliberately create the situation described above. Namely, the density or equivalent circulating density of the upwardly returning mud is below the pore pressure of the rock being drilled, causing gas, oil, or water in the rock to enter the well-bore from the rock being drilled. This may also result in increased drilling rates but also the well to flow if the rock permeability and porosity allowed sufficient fluids to enter the well-bore.

10 In this drilling environment it is general practice to provide a variety of blowout preventers to control any loss of control incidents or blowouts that may occur.

A variety of techniques have been utilized for underbalanced or dual gradient drilling. Generally, they involve providing a density lowering component to the returning drilling mud. Gases, seawater, and glass beads have been injected into the returning mud flow to reduce its density.

In deep subsea applications, a number of problems may arise. Because of the pressures involved, everything becomes significantly more complicated. The pressure that bears down on the formation includes the weight of the drilling mud, whereas the pressure in the shallow formations is dictated by the weight of seawater above the formation. Because of the higher pressures involved, the drilling mud may actually be injected into the formation,

fracture it and may even clog or otherwise foul the formation itself, severely impairing potential hydrocarbon production.

Brief Description of the Drawings

5 Figure 1 is a schematic depiction of one embodiment of the present invention;

Figure 2 is an enlarged schematic depiction of the subsea shut-off assembly shown in Figure 1 in accordance with one embodiment of the present invention;

10 Figure 3 is an enlarged, schematic, cross-sectional view of the spool 34 shown in Figure 2 in accordance with one embodiment of the present invention; and

Figure 4 is a schematic cross-sectional view of the rotating head shown in Figure 1 in accordance with one
15 embodiment of the present invention.

Detailed Description

In some embodiments of the present invention, both drilling and production of fluids from a formation may occur in an underbalanced condition. As used herein,
20 "underbalanced" means that the weight of the drilling mud is less than the pore pressure of the formation. As used herein, "dual gradient" refers to the fact that the density of fluid, at some point along its course, moving away from a drill bit, is lower than the density of the fluid moving
25 towards the drill bit. Dual gradient techniques may be

used to implement underbalanced drilling. The creation of a dual-gradient or underbalanced condition may be implemented using any known techniques, including the injection of gases, seawater, and glass beads, to mention a few examples.

Referring to Figure 1, a drilling and production apparatus 11 may include a rotating head 10 which rotates a string for purposes of drilling a well in a subsea formation SF. The rotating head 10 rotates the string through a surface blowout preventer (BOP) stack 12. The surface blowout preventer stack 12 may include annular blowout preventers that control the flow of fluid moving upwardly from the wellhead to the overlying floating rig 14.

The rig 14 may be tensioned using ring tensioners 16, coupled by a pulleys 54 to hydraulic cylinders 56 to create a tensioning system 50. The tensioning system 50 allows the upper portion of the apparatus 11 to move relative to the lower portion, for example in response to sea conditions. The system 50 allows this relative movement and adjustment of relative positioning while maintaining tension on the casing 22, which extends from the floating rig 14 downwardly to a subsea shutoff assembly 24.

The surface portion of the apparatus 11 is coupled by a connector 20 to the casing 22. The casing 22 is connected to the lower section of the apparatus 11 via a

disconnectable latch 72 located below the sea level WL.
The latch 72 may be hydraulically operated from the surface
to disconnect the upper portion of the apparatus 11 from
the lower portion including the subsea shutoff assembly 24.

5 Also provided on the rig 14 is a source of fluid that
is of a lower density than the density of mud pumped
downwardly through the casing 22 from the surface in one
embodiment of the present invention. The lower density
fluid may be provided through the tubing 60.

10 A hanger system 58 includes a tensioner 58 that rests
on a support 56. The hanger system 58 tensions the
tensioned tubing 26 that extends all the way down to a
disconnectable subsea latch 74 above the subsea shutoff
assembly 24. Like the latch 72, the latch 74 may be
15 remotely or surface operated to sever the tubing 26 from
the subsea shutoff assembly 24. In one embodiment, the
support 56 may include hydraulic ram devices that move like
shear ram blowout preventers to grip the tubing 26.

20 The rate of lower density fluid flow through the
tubing 26 from the surface may be controlled from the
surface by remotely controllable valving in the subsea
shutoff assembly 24, in one embodiment. It is advantageous
to provide this lower density fluid from the surface as
opposed to attempting to provide it from a subsea location,
25 such as within the subsea shutoff assembly 24, because it

is much easier to control and operate large pumps from the rig 14.

The subsea shutoff assembly 24 operates with the surface blowout preventer stack 12 to prevent blowouts.

5 While the surface blowout preventer stack 12 controls fluid flow, the subsea shutoff assembly 24 is responsible for cutting off or severing the wellhead from the portions of the apparatus 11 thereabove, using shear rams 30a and 30b as shown in Figure 2. Thus, the casing 22 may be coupled
10 by connector 28a to the shear ram 30a. The shear ram 30a is coupled by a spool 34 with flanges 32a and 32b to the shear ram 30b. The shear ram 30b may be coupled through the flange 38 to a wellhead connector 28b, in turn connected to the wellhead.

15 As shown in Figure 2, the tubing 26 connects to a remotely controlled valve 36 that controls the rate of lower density fluid flow through the tubing 26 to the interior of the spool 34. The inlet from the tubing 26 to the spool 34 is between the two shear rams 30a and 30b.

20 The injection of lower density fluid, as shown in Figure 3, makes use of the remotely controlled valve 36 on a spool 34. The spool 34 may have drilling mud, indicated as M_{IN} , moving downwardly through the casing 22. The returning mud, indicated as M_{OUT} , extends upwardly in the
25 annulus 46 surrounding the string 40 and annulus 44. Thus, lower density fluid may be injected, when the valve 36 is

opened, into the returning mud/hydrocarbon flow to lower its density.

An underbalanced situation may be created as a result of the dual densities of mud in one embodiment. Namely,
5 mud above the valve 36 may be at a lower density than the density of the mud below the valve 36, as well as the density of the mud moving downwardly to the formation. The valve 36 may include a rotating element 37 that allows the valve 36 to be opened or controlled. As an additional
10 example, the valve 36 may be a pivoted gate valve with a hydraulic fail safe that automatically closes the valve in the event of a loss of hydraulics. The valve 36 may enable the extent of underbalanced drilling to be surface or remotely controlled depending on sensed conditions,
15 including the upward pressure supplied by the formation. For example, the valve 36 may be controlled acoustically from the surface.

Thus, in some embodiments of the present invention, flow control may be done most effectively at the surface,
20 whereas shutoff control is done on the seafloor bed. The pumping of the lower density fluid is also done on the surface, but its injection may be done at the subsea shutoff assembly 24, in one embodiment between the shear rams 30a and 30b.

25 The rotating head 10, shown in more detail in Figure 4, is coupled to the surface blowout preventer stack 12 at

a joint 70. Returning fluid, indicated as M_{OUT} , is passed through a valve 68 to an appropriate collection area. The collection area may collect both mud with entrained debris, as well as production fluids such as hydrocarbons. The
5 production fluids may be separated using well known techniques.

The upward flow of the fluid M_{OUT} is constrained by a packer 62. In one embodiment, the packer 62 is a rubber or resilient ring that seals the annulus around the string 40
10 and prevents the further upward flow of the fluids. At the same time, the packer 62 enables the application of a rotating force in the direction of the circular arrow from the rotating head 66 to the string 40 for purposes of drilling. Seals 65 may be provided between a telescoping
15 joint 64 and the rotating head 66 as both drilling and production may be accomplished in an underbalanced situation.

Thus, in some embodiments of the present invention, a subsea shutoff assembly 24 may be provided to cut off the
20 string in the event of a failure, such as a blowout. At the same time, surface annular blowout preventers control fluid flow. Dual gradient drilling may be achieved through the provision of fluid from the surface through a side inlet into the region between the upper and lower ram type
25 shear blowout preventers 30. Through the provision of the separate tubing 26 with a remotely operable latch 74,

appropriate volumes of fluid can be achieved that would not be available with conventional kill and choke lines. The tubing 26 for providing the density control fluid may be both tensioned and latched. As a result, dual gradient
5 production and drilling may be achieved in some embodiments of the present invention.

While the present invention has been described with respect to a limited number of embodiments, those skilled in the art will appreciate numerous modifications and
10 variations therefrom. It is intended that the appended claims cover all such modifications and variations as fall within the true spirit and scope of this present invention.
